1 Introduction

2 Theoretical Background/Literature Review

2.1 FDI

2.2 PSM

Since (I guess) we will be focussing on ATE rather than ATT, we need to satisfy the following two assumptions:

1. Assumption: **Unconfoundedness (CIA)**

"[G]iven a set of observable covariates X which are not affected by treatment, potential outcomes are independent of treatment assignment" (Caliendo et al., 2008, p. 35)

2. Assumption: **Overlap**

"persons with the same X values have a positive probability of being both participants and nonparticipants" Caliendo and Kopeinig (2008, p. 35)

→ if Assumption 1 holds, all biases due to observable components can be removed by conditioning on the propensity score (Imbens, 2004).

Binary Treatment

Difference between logit and probit lies in the link function. Logit assumes a log-distribution of residuals, probit assumes a normal distribution. Heteroskedastic probit models can account for non-constant error variances → Check for heteroskedasticity?

Multiple Treatments

The multinomial probit model is the preferable option compared to logit. Alternatively, just run several binary ones (more complicated but also more robust to errors).

Variable selection

- outcome variable must be independent of treatment conditional on the pscore (CIA)
- Only variables that influence simultaneously the participation decision and the outcome variable should be included (based on theory and empirical findings)

- variables should either be fixed over time or measured before participation (include only variables unaffected by participation)
- choice of variables should be based on economic theory and previous empirical findings

Tests for variable selection

Strategies for the selection of variables to be used in estimating the propensity score: ...

3 Data and Descriptive Analysis

Our analysis is based on observational firm-level data. The dataset comprises 11,323 firms, of which 4,460 received FDI in 2016. The FDI can be divided into three subcategories. Table 1 shows the frequencies of each type of FDI in our sample. Among the recipients of FDI, most firms (1,965) received domestic market seeking FDI. 1,555 firms received technology intensive FDI and the remaining 640 firms received exports oriented FDI. The TFP outcome was measured in 2017. We standardize ¹ the outcome variable to make its interpretation more intuitive.

Table 1: Frequency of FDI Types

FDI type	Abs. Freq.	Rel. Freq.
No FDI	6,863	61%
Exports oriented FDI	940	8%
Technology intensive FDI	1,555	14%
Domestic market seeking FDI	1,965	17%
Total	11,323	100%

A set of categorical and continuous control variables was measured in 2015 (one year prior to the firms receiving FDI). Table 2 provides an overview of the categorical variables and the frequencies of each category in our sample. The categorical variables are included as factor variables in the subsequent analysis. The port variable indicates whether a firm has access to a port within 500km. The legal ownership of a firm is captured in the ownership variable, where state owned firms represent the base group. The technology intensity of the industry the respective firm is operating in, is measured in

¹Using Z-score standardization

four categories from low- to high-tech, low-tech being the base group. The R&D dummy indicates whether a firm has invested in Research and Design in 2015.

Table 2: Summary Statistics of Categorical Covariates

	Abs. Freq.	Rel. Freq.
Port^a		
No	7,366	65.05
Yes	3,957	34.95
Ownership		
Listed company	909	8.03
Subsidiary	2,630	23.23
Independent	4,593	40.56
State owned	3,191	28.18
Technology Intensity		
Low-tech	4,194	37.04
Medium low-tech	1,685	14.88
Medium high-tech	3,539	31.25
High-tech	1,905	16.82
R&D^b		
No	9,951	87.88
Yes	1,372	12.12

^a Indicates whether a firm has access to a port within 500km.

^b Indicates whether a firm has invested in R&D in 2015.

The summary statistics of the continuous variables wages, Total Factor Productivity (TFP), firm size (measured in number of employees), debts and the firms' export intensity are displayed in Table 3. The variables wages, employment and, to a lesser extent, debts show large differences between their mean and median values, hinting at the existence of outliers in the sample. Log transforming the skewed variables is an easy way of reducing the influence of extreme values.

However, during placebo estimation with a different outcome it became clear that not taking the logarithm of employment yields better covariate balance in all models. Therefore we use the untransformed variable. Noting an extreme value in the variable (see Figure 1) we added a robustness check that excluded this observation, yielding essentially the same results.

To further motivate the use of matching estimators in estimating the effect of FDI

Table 3: Summary Statistics of Continuous Covariates

	Mean	Median	Sd	Min	Max
Wages	1,967 ^a	1,538	50,990 ^a	0.00065	5,519,000 ^a
TFP	3.041	3.032	2.047	-5.359	11.36
Employment	7,111	81.39	117,155	0.00197	8,824 ^a
Debt	1.762	1.649	0.634	0.819	3.668
Export intensity	0.159	0.154	0.0798	0.0103	0.483

Note: All variables in levels.

^a In Thousands

on a firm's TFP, the differences in means between the firms that received FDI and the firms that did not are displayed in Table 4. The t-tests show significant differences in all observable characteristics, meaning that there is in fact selection into treatment.

4 Empirical Specification

In order to evaluate the causal effect of FDI on Total Factor Productivity (TFP) we estimate our main model described in equation (1) using nearest-neighbour matching with one neighbour and with replacement. Second, we also estimate a nearest neighbour model with 5 neighbours with replacement and a caliper of 0.05. Further, we use inverse probability weighting (IPW) and augmented-inverse probability weighting (AIPW) estimators. Since we have a large sample, the different estimators should all yield essentially the same results.

For the matching, weighting and regression adjustment models we use the same specification including the before-mentioned categorical and continuous variables. We unlog employment to improve covariate balance. We do not include the export variable as a matching covariate, since together with technology it predicts treatment too well and nearly eliminates overlap. As propensity score matching requires that all covariates which affect both outcome and likelihood of treatment, we can exclude export since it does not influence the outcome variable. As Girma et al (2004) show, productivity increases exports, not the other way around. We do not include the port variable for the same theoretical reason.

$$TFP = \beta_0 + \beta_1 FDI + \beta_2 X_{i2015} + \epsilon_i$$

Table 4: Difference in Pre-Treatment Covariate Means

	(1) Control	(2) Treatment	T-test Difference (1)-(2)
Technology intensity	2.565 (0.014)	1.838 (0.015)	0.728***
Access to port	0.273 (0.005)	0.467 (0.007)	-0.194***
Log wages	7.529 (0.046)	7.031 (0.057)	0.498***
TFP	3.185 (0.025)	2.821 (0.030)	0.364***
Log employment	3.766 (0.037)	5.405 (0.041)	-1.639***
Log debts	0.511 (0.004)	0.493 (0.005)	0.019***
Export intensity	0.131 (0.001)	0.204 (0.001)	-0.073***
R&D dummy	0.117 (0.004)	0.128 (0.005)	-0.012*
Observations	6863	4460	

Notes: Columns (1) and (2) show the pre-treatment covariate means of the control and treatment group respectively. Standard errors are displayed in paratheses. The values displayed for t-tests are the differences in the means across the groups. ***, **, and * indicate significance at the 1, 5, and 10 percent critical level.

Figure 1: Outliers in Employment Variable

where

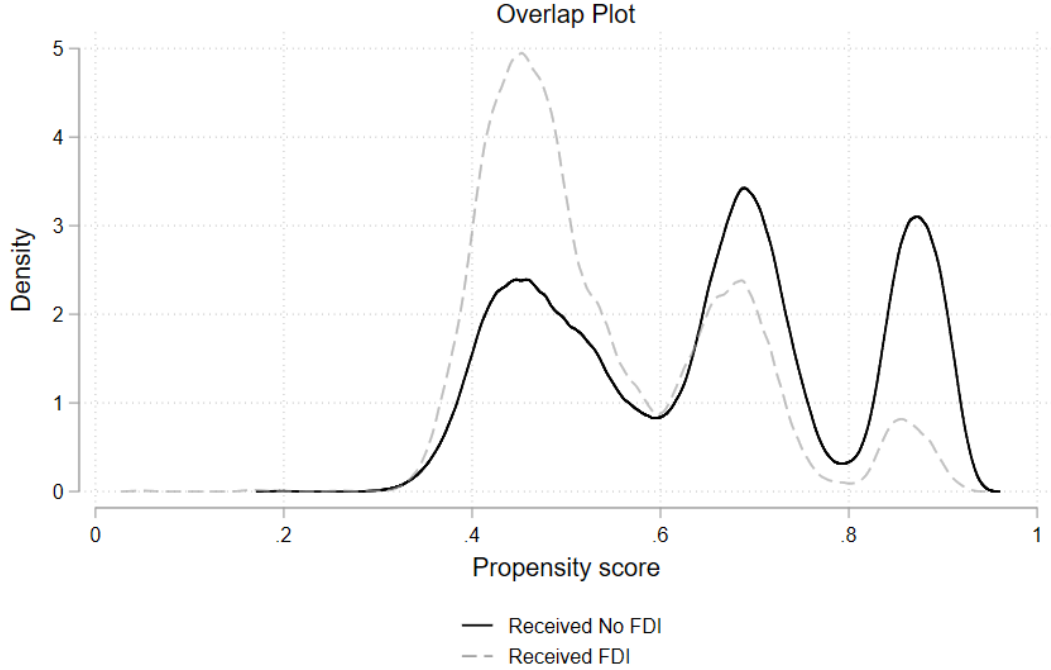

- FDI is a non-random treatment variable. It takes value 1 in case of treatment, 0 otherwise;
- X_{i2015} describes control variables and consists of following pre-treatment covariates: Ownership, Technology Intensity, Research&Development, logarithm of Wages, Total Factor Productivity, Employment and Debts

Our matching model is thus a logit regression of TFP in 2017 on Ownership, Technology Intensity, Research&Development, logarithm of Wages, TFP in 2015, Employment and Debts. This very good overlap and covariate balances (the latter discussed in more detail down below). Figure two shows proof of sufficient overlap for a matching analysis.

4.1 Effect of FDI on TFP

The main findings of this paper are displayed in Table 5. It reports the Average Treatment Effects (ATE) for FDI on TFP. Across estimators, we find large and highly significant

Figure 2: Overlap in Main Model

coefficients showing that receiving FDI increases TFP of companies on average. The reported coefficients differ only slightly in magnitude, suggesting that the matching model is correctly specified. Column (1) shows the results of a one-to-one propensity score matching with replacement. Receiving FDI increases Factor Productivity by 13% of a standard deviation for the average company. Slightly lower results are obtained from a propensity score matching with five nearest neighbors and a caliper of 0.05 as well as for the invers IPW. The doubly robust AIPW-estimator is slightly larger than the main model, but the estimators are within three percent of each other.

Checking the covariate balances of our models, we prefer the one-to-one propensity score matching as it gives us the best covariate balance of all the estimators *see Appendix*.

4.2 Robustness of Results

In order to test for the sensitivity of our main findings, we perform the nearest-neighbour matching with one neighbor and replacement for alternative model specifications. The results of these robustness checks are reported in Table 6. The positive and significant

Table 5: ATE of FDI on TFP

	NN1	NN5 ^a	IPW	AIPW
	(1)	(2)	(3)	(4)
FDI2016	0.130*** (0.015)	0.114*** (0.011)	0.122*** (0.007)	0.142*** (0.003)
PO Means			-0.068*** (0.010)	-0.057*** (0.009)
Observations	11,323	11,318	11,323	11,323

Notes: Standard errors in parentheses. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$. Covariates include, unless otherwise specified: Ownership, Technology Intensity, Research&Development, logarithm of wages, Total Factor Productivity, Employment and Debts.

All reported coefficients are normalized for better interpretation.

^a We use the Propensity Score Matching method with five nearest neighbours and replacement as well as a 0.05 caliper.

effect of FDI on TFP persists through all specifications, confirming our main results that foreign equity participation increases the productivity of firms.

In column (1), we add interaction terms of the dummy variables with the continuous regressors to our set of covariates. This is widely practiced to improve covariate balance (Caliendo and Kopeinig, 2008). However, the covariate balance does not improve with the inclusion of interaction terms, suggesting that interactions do not increase the quality of matching in our case.² Our estimate of the Average Treatment Effect of FDI on productivity slightly increases by 0.022 standard deviations compared to the effect reported in Table 5.

Our results could further be biased by the outliers in the employment variable (see Figure 1). While most of the firms' numbers of employees are concentrated around the mean of 7,111, we are concerned about two observations with extreme values: one firm with over eight million employees, and another one that apparently employed more than four million people in 2015.³ To check whether these outliers influence our main findings, we exclude the two extreme observations. The results reported in column (2) show no significant change in the average treatment effect. In our main specification, we have

²The same holds true when interacting only dummy variables, only continuous variables or all variables.

³Given the limited information our dataset contains, we cannot be sure in which unit employment is measured. We therefore suppose that the common definition of employment being the number of hired employees holds. Regardless of the measurement unit of employment, the outliers might be problematic.

further assumed that a port being within 500 km of the firm does not influence total factor productivity. Column (3) confirms that this is indeed the case, as the results do not change with the inclusion of the dummy variable port in our set of covariates.

Table 6: Robustness of Results^a

	Including Interactions ^b (1)	Excluding Outliers ^c (2)	Including Port ^d (3)	Effect on the Treated (4)
ATE	0.152*** (0.016)	0.127*** (0.015)	0.125*** (0.019)	
ATT				0.127*** (0.017)
Observations	11,323	11,321	11,323	11,323

Notes: Standard errors in parentheses. *** p<0.01, ** p<0.05, * p<0.1.

^aAll specifications use the Propensity Score Matching method with one nearest neighbor and replacement. Covariates include, unless otherwise specified: Ownership, Technology Intensity, Research&Development, logarithm of Wages, Total Factor Productivity, Employment and Debts.

^b Interacting dummy variables (Ownership, Technology Intensity, Research & Development) with continuous variables (Logarithm of wages, Total Factor Productivity, Employment and Debts).

^c Two observations with extreme values of Employment 2015 above four million are excluded.

^d Adding a dummy variable indicating whether a port lies within 500km of the firm to the set of covariates.

Finally, column (4) reports the average treatment effect on the treated (ATT) of the nearest neighbor matching with one neighbor and replacement. Because we assume that treatment is not exogenous, we might find stronger effects of treatment on the treated. This would be the case if those firms receiving treatment are also the ones benefiting more from it. However, our estimate in column (4) reports an ATT that is very similar to the average treatment effect for the hypothetical case that all firms had received FDI.

Notes to Table:

- Effects differ by TECH intensity
- Higher Standard Errors
- Suggests higher effects for all industries but Medium Low-tech

Table 7: ATE by Technology Intensity of Industry

	Low-Tech Industry (1)	Medium Low-Tech Industry (2)	Medium High-Tech Industry (3)	High-Tech Industry (4)
FDI2016	0.160*** (0.020)	0.086*** (0.028)	0.172*** (0.019)	0.180*** (0.054)
Observations	4,194	1,685	3,539	1,905

Notes: Standard errors in parentheses. *** p<0.01, ** p<0.05, * p<0.1.

- Weighted mean of ATEs: 0.15750992

5 Analysis by Type

To further test the robustness of our results, we continue our analysis by looking at potential heterogeneity of the treatment effect across types of FDI. Recall the three types of FDI from table 1 as Exports oriented, Technology intensive and Domestic market seeking, with the latter being most common and the first being least common. We test the possibility that one specific type of Investment single handedly drives our previous results. It is possible, that for example only exports-oriented increased factor productivity while the other two types had little or no impact.

We estimate an augmented IPW model with multi-valued treatment effects. The matching covariates are the same as in the previous model and the regression adjustment specification is the same as that for propensity score estimation. The covariate balance is good, but the variance ratio of employment (unlogged) is a borderline case.⁴

Second, we estimate an IPW model to check if it yields similar estimates without regression adjustment. The covariate balance in this model is practically the same. Finally, we estimate a set of AIPW models where we restrict the sample to one type of treatment each. This allows for the IIA assumption to be relaxed which is required for the Multinomial Logit models. The separate models have worse covariate balance than the first two but are borderline acceptable. The overlap assumption is satisfied for all treatment levels as can be seen in graph 3.

In Table 8 the results from the type-wise analysis are shown. In the AIPW Multinomial

⁴Unfortunately an AIPW model with any interactions did not converge, so it was impossible to try and improve the balance this way.

specification the ATE of different types of FDI are within half a percent of each other. This suggests, that all types of FDI increase factor productivity by essentially the same margin. The estimated effect size is close to the one estimated for FDI in table 2. In the IPW specification the differences slightly larger but still within 5% of a standard deviation of each other. The separate logit models also yield essentially the same effect sizes as the multinomial specification. Since the AIPW estimator is doubly robust (assuming correctly specified regression adjustment models) models (1) and (3) provide us with strong evidence of homogenous effects.

include the reference in the actual file as follows:

?

(Caliendo et al., 2008, p. 35)

Thoughts on what we could write for discussion/limits of our study:

1. Do not know much about the context of the treatment (so cannot really rule out anticipation-effects?)
2. Would have been interesting to extend the study to several years after the treatment. Do effects persist? Do they vanish?
3. Might depend on firm size (see Aitken & Harrison 1999 → will include citation): find positive within-plant effects and spillover effects on TFP for small firms only (less than 50 employees)
4. Do not measure spillovers on plants that have not received FDI
5. Do not have sector-specific data → TECH variable has only 4 categories; e.g. in order to measure spillover effects from other firms in sector this would be necessary (i.e. if a foreign firm is more innovative)

One shortcoming of our analysis is the missing capability to explain the mechanisms behind the observed treatment effects. We do not distinguish between within-firm effects and spillover effects from firms receiving FDI to other firms. That is, the literature

on spillover effects typically suggests spillovers within sectors rather than across sectors (SOURCE) and higher spillover effects on nearby firms or firms that are trading factor inputs with foreign-owned companies (SOURCE). Due to the limited information on a firm's sector and location, we are unable to measure spillover effects.
